Manipulating and Joining Data in R with dplyr

Lubov McKone & Chen Chiu Johns Hopkins Libraries Data Services

2024-04-11

This webinar will be recorded!

Your continued participation indicates your consent to be recorded. This recording may be shared with the JHU community.

Any questions you ask verbally or in chat will be edited to protect your identity.

JHU Data Services

We help faculty, researchers, and students find, use, manage, visualize, and share data.

- Find out more at dataservices.library.jhu.edu
- Email us for a consultation at dataservices@jhu.edu
- Share your research data at archive.data.jhu.edu

What you will learn today

- How to reshape data using the powerful dplyr package
- How to use the pipe > to simplify code
- How to join two datasets together using different approaches and conditions
- Additional resources for manipulating and joining data using dplyr

You should have:

- A template R script that we will fill out today called class_script_blank.R
- dplyr cheatsheet
- Basic knowledge of R
 - Installing and loading packages
 - Basic terminology of R or programming in general

Why reshape data?

- Calculate new variables to analyze
- Summarize data differently to suit your unit of analysis
- Rearrange or sort data to make it easier to visualize

Libraries

Today we'll be using the tidyverse library, which includes dplyr.

```
1 library(tidyverse)
Warning: package 'tidyverse' was built under R version 4.3.2
\checkmark dplyr 1.1.2 \checkmark readr 2.1.4
\checkmark forcats 1.0.0 \checkmark stringr 1.5.0
\checkmark qqplot2 3.4.2 \checkmark tibble 3.2.1

√
 lubridate 1.9.2 
√
 tidyr 1.3.0
√ purrr 1.0.1
- Conflicts -
                                                    — tidyverse conflicts()
X dplyr::filter() masks stats::filter()
X dplyr::lag() masks stats::lag()
i Use the conflicted package (<a href="http://conflicted.r-lib.org/">http://conflicted.r-lib.org/</a>) to force all
conflicts to become errors
```

Review: reading and viewing data

- 1 # we'll be looking at data on Groundhog predictions
 2 groundhogs <- readr::read_csv('https://raw.githubusercontent.com/rfordatasc</pre>
- 3 predictions <- readr::read_csv('https://raw.githubusercontent.com/rfordatas</pre>

You can view a dataframe in R using View() or by clicking the object in the environment pane.

Let's take a look at our groundhog predictions dataset:

year <dbl></dbl>	shadow <lgl></lgl>
1886	NA
1887	TRUE
1888	TRUE
1889	NA
1890	FALSE
	<dbl> 1886 1887 1888 1889</dbl></dbl></dbl></dbl></dbl></dbl></dbl></dbl></dbl></dbl></dbl>

id <dbl></dbl>	year <dbl></dbl>	shadow <lgl></lgl>
1	1891	NA
6 rows 1-3 of 4 column	ns	

Our task today

- We are groundhog mythbusters and our goal is to collect some summary statistics about the groundhog prediction phenomenon.
- Our main question is whether different groundhogs are more or less likely to predict an early spring.
- Over the course of this workshop, we'll be creating summary tables that will set us up for further visualization and analysis.

The dplyr package

- dplyr is a "grammar" of data manipulation
- dplyr is a set of R functions that work together to help you solve the most common data manipulation challenges, like:
 - Filtering out certain rows and sorting your data
 - Calculating a new column based on existing columns
 - Grouping and summarizing data
 - Joining data from different sources

dplyr grammar

- dplyr's core is a set functions that can be divided into 4 groups based on what they operate across:
 - rows
 - columns
 - groups
 - tables
- We'll call these the dplyr *verbs*
- dplyr also contains a number of useful *helper functions* that operate on single values or arrays. We'll introduce those along the way.

anatomy of a dplyr verb

In every dplyr verb:

- the first argument is always dataframe
- the output is always a new dataframe
- arguments with a . in front of them are settings for the function, not column names

the pipe

- Each verb does one thing very well, so you'll typically chain together multiple verbs. The **pipe** helps you do this by passing the result of every action onto the next action.
- The pipe is represented in R as |>. Everything to the left of the pipe is passed as the first argument to the thing immediately to the right of the pipe.
- x > f(y) is equivalent to f(x, y)
- x | > f(y) | > g(x) is equivalent tog(f(x,y), z)
- A The pipe does not save new variables automatically

row verbs

- filter(): keep rows based on the value of one or more columns
- arrange(): changes the row order based on one or more columns
- distinct(): finds all the unique rows based on the values of one or more columns

row verbs: filter()

- filter(): keep rows based on the value of one or more columns
- You can compose conditions using ==, >, <, >=, <=, !=,
 and include multiple conditions using & or |
- The %in% operator can serve as a combination of | and ==

row verbs: filter()

- 1 # find groundhog predictions from 2020
- 2 filter(predictions, year == 2020)

id <dbl></dbl>	year <dbl></dbl>	shadow <lgl></lgl>
1	2020	FALSE
2	2020	FALSE
3	2020	TRUE
4	2020	TRUE
5	2020	TRUE
6	2020	FALSE
7	2020	TRUE
8	2020	FALSE
9	2020	TRUE
10	2020	FALSE

1-10 of 67 rows | 1-3 of 4 colu... Previous 1 2 3 4 5 6 7 Next

```
filter(predictions, year == 2020 | year == 2021)
              id
                                                                            shadow
                                        year
           <dbl>

1909

TRUE

filter(): useful helper functions

- between() tests if a variable falls between two values (inclusive)
- near() tests if a variable is within a certain range of a given number (you can set the tolerance)
- is.na() tests whether the variable is NA. Use is conjunction with! to filter for non-NA values.

row verbs: arrange()

arrange(): changes the row order based on one or more
columns

You can wrap the columns with desc() to sort in descending order

1	#	sort	our	prediction	ns by	year
2	aı	rrange	e(pre	edictions,	year)

•	shadow <lgl></lgl>	year <dbl></dbl>	id <dbl></dbl>
	NA	1886	1
	TRUE	1887	1
	TRUE	1888	1
	NA	1889	1
	FALSE	1890	1
	NA	1891	1
	NA	1892	1
	NA	1893	1
	NA	1894	1
	NA	1895	1

Previous 1 2 3 4 5 6 14 Next

1 # sort our predictions by year
2 arrange(predictions, desc(year))

•	shadow <lgl></lgl>	year <dbl></dbl>	id <dbl></dbl>
	TRUE	2023	1
	FALSE	2023	2
	FALSE	2023	3
	TRUE	2023	4
	FALSE	2023	5
	TRUE	2023	6
	FALSE	2023	7
	FALSE	2023	8
	TRUE	2023	9
	FALSE	2023	10

Previous 1 2 3 4 5 6 14Xext

row verbs: distinct()

distinct(): finds all the unique rows based on the values
of one or more columns

- Without any additional inputs, distinct() finds and keeps the first occurence of all unique rows
- You can optionally supply one or more columns to check for distinct combinations of
- If you want to retain all of the columns, set the
 .keep_all argument to TRUE

```
1 # find unique years that predictions were made
2 predictions |>
3 distinct(year)
```

	year <dbl></dbl>
	1886
	1887
	1888
	1889
	1890
	1891
	1892
	1893
	1894
	1895
1-10 of 138 rows	Previous 123456 14Next

Let's put it all together!

- Remove rows with no prediction record
- Remove duplicate predictions
- Sort the result by year, descending
- Assign the result to predictions, overwriting the previous dataframe

```
1 # create a subset of your data where "shadow" has a value of either TRUE or
2 predictions <- predictions |>
3   filter(shadow %in% c(TRUE, FALSE)) |>
4   distinct(year, id, .keep_all = TRUE) |>
5   arrange(desc(year))
```

group verbs

- group_by() groups your dataframe
- summarize() reduces the dataframe to a summary table with one row for each group and one or more calculations by group

group verbs: group_by()

group_by() groups your dataframe

On it's own, it doesn't change your data. But you can feed the "grouped" output into other special functions to apply different transformations to each group in your data.

```
# group predictions by year
predictions |>
   group by (year)
              id
                                                                         shadow
                                       year
           <dbl>
                                      <dbl>
                                                                            < |g| >
               1
                                       2023
                                                                           TRUE
               2
                                       2023
                                                                          FALSE
               3
                                       2023
                                                                          FALSE
               4
                                       2023
                                                                           TRUE
               5
                                                                          FALSE

1-10 of 1,317 rows | 1-3 of 4 ... Previous 1 2 3 4 5 6 13\(\)ext

group verbs: summarize()

- summarize() reduces the dataframe to a summary table with one row for each group and one or more calculations by group
- The syntax is dataframe |> group_by(column) |> summarize(new_variable = summary_function(..))
- One of the most important summaries is n(), which counts the observations (rows) in each group.
- Let's try it together: How many predictions were made in each year?

n()within summarize()

```
1 # How many predictions were made in each year?
2 predictions |>
3   group_by(year) |>
4   summarize(n_predictions = n()) |>
5   arrange(desc(year))
```

year	n_predictions
<dbl></dbl>	<int></int>
2023	70
2022	71
2021	60
2020	65
2019	60
2018	61
2017	57
2016	51
2015	51

year	n_predictions
<dbl></dbl>	<int></int>
2014	48
1-10 of 128 rows	Previous 1 2 3 4 5 6 13Next

summarize() helper functions

- Other powerful summary functions include:
 - n_distinct(): counts the number of distinct values of a given column within a group
 - max() and min(): finds the max and min value of a given column within a group
- Exercises:
 - How many different groundhogs made predictions each year?
 - What is the first year each groundhog made a prediction?

summarize() helper functions

```
1 # How many different groundhogs made predictions each year?
2 predictions |>
3   group_by(year) |>
4   summarize(n_groundhogs = n_distinct(id)) |>
5   arrange(desc(n_groundhogs))
```

year	n_groundhogs
<dbl></dbl>	<int></int>
2022	71
2023	70
2020	65
2018	61
2019	60
2021	60
2017	57
2015	51
2016	51

year	n_groundhogs

sum() within summarize()

- sum(): finds the sum of a given column within a group. You can also specify conditions within sum() to calculate the number of records within a group that meet a certain condition.
- Exercise: Let's return to our dataframe with the number of predictions in each year. How would we add a column for the number of shadows seen in each year?

sum() within summarize()

```
1 # Let's return to our dataframe with the number of predictions in each year
2 # How would we add a column for the number of shadows seen in each year?
3 predictions |>
4 group_by(year) |>
5 summarize(n_predictions = n(),
6 n_shadows = sum(shadow == TRUE))
```

year	n_predictions	n_shadows
<dbl></dbl>	<int></int>	<int></int>
1887	1	1
1888	1	1
1890	1	0
1898	1	1_
1900	1	1_
1901	1	1
1902	1	0
1903	1	1
1904	1	1

year	n_predictions	n_shadows
<dbl></dbl>	<int></int>	<int></int>
1905	1	1
1-10 of 128 rows	Previous 12	3 4 5 6 13Next

Your turn! Create a dataframe with three variables:

- groundhog id
- the number of total predictions each groundhog has made
- the number of times each groundhog has seen it's shadow.

checkpoint: group verbs

```
# Create a dataframe with 3 variables:
 # groundhog id
3 # the number of total predictions each groundhog has made
 # the number of times each groundhog has seen its shadow
 predictions |>
    group by(id) |>
   summarize(n predictions = n(),
              n shadows = sum(shadow == TRUE))
8
```

id <dbl></dbl>	n_predictions <int></int>	n_shadows <int></int>
1	128	108
2	91	72
3	60	25
4	55	23
5	45	18
6	40	12
7	40	4

9	30	10
10	28	9
1-10 of 75 rows	Previous 12	3 4 5 6 8 Next

column verbs

Now that we've calculated some summary variables within the groups that interest us (groundhog and year), we might want to use those summary variables to calculate more new variables.

- mutate() adds new columns calculated from existing columns
- select() keeps a subset of columns
- rename() renames columns

column verbs: mutate()

mutate() adds new columns calculated from existing
columns

• By default, columns are added on the left side of the dataframe. You can use the .before or .after to specify where the new variable should fall

```
1 # calculate how many characters are in the details field and put the variab
2 predictions |>
3 mutate(details length = nchar(details), .after = id)
```

id <dbl></dbl>	details_length <int></int>	year <dbl></dbl>	shadow <lgl></lgl>
1	158	2023	TRUE
2	NA	2023	FALSE
3	24	2023	FALSE

id <dbl></dbl>	details_length <int></int>	year <dbl></dbl>	shadow <lgl></lgl>
4	NA	2023	TRUE
5	NA	2023	FALSE
6	NA	2023	TRUE
7	NA	2023	FALSE
8	NA	2023	FALSE
9	NA	2023	TRUE
10	NA	2023	FALSE

1-10 of 1,317 rows | 1-4 of 5 ... Previous 1 2 3 4 5 6 13\(\text{Next} \)

re-coding data with mutate()

if_else() tests for a condition and returns one value if true and another if false.

```
1 # create a column that indicates whether the prediction was made by Punxata
  predictions |>
    mutate(phil = if else(id == 1, 'TRUE', 'FALSE'))
                id
                                                                           shadow
                                         year
             <dbl>
                                                                             \langle |g| \rangle
                                        <dbl>
                                                                            TRUE
                 1
                                         2023
                                         2023
                                                                            FALSE
                 3
                                         2023
                                                                            FALSE
                                         2023
                                                                            TRUE
                 5
                                         2023
                                                                            FALSE
                                         2023
                                                                            TRUE
                 6
                                                                            FALSE
                                         2023
                                         2023
                                                                            FALSE
```

1-10 of 1,317 rows | 1-3 of 5 ... Previous 1 2 3 4 5 6 13\(\text{Next} \)

column verbs: select() and rename()

- select() keeps a subset of columns
 - You can select by name, series, test for data type (select(where(is.character()))) or use other helper functions such as starts_with(), ends_with(), or contains()
 - You can rename variables as you select them with = ,
 with the new name on the left and old on the right
- rename() works the same way as renaming in selectwith =

checkpoint: put it all together!

Let's return to our original research question: Are certain groundhogs more likely to see their shadow than others? Working off of our table with the number of predictions and number of shadows seen per groundhog, lets:

- Add a column called shadow_percent that gives the percentage of time each groundhog sees its shadow
- Filter for groundhogs with more than 5 predictions
- Keep only the variables id and shadow_percent, and rename id to groundhog_id
- Assign the result to a variable groundhog_predictions

checkpoint: put it all together!

```
groundhog predictions <- predictions |>
    group by (id) |>
    summarize(n predictions = n(),
              n shadows = sum(shadow == TRUE)) |>
    mutate(shadow percent = n shadows/n predictions) |>
5
    filter(n predictions > 5) |>
   select(id, shadow percent) |>
    rename(groundhog id = id)
8
```

table verbs: joining data

We've done a lot with the mere 4 variables in our predictions table!

What if we wanted to enhance our data with more information about each groundhog from the groundhogs table?

1 head(groundhogs)				
id	slug	shortname	name	
<dbl></dbl>	<chr></chr>	<chr></chr>	<chr></chr>	
1	punxsutawney-phil	Phil	Punxsutawney P	
2	octoraro-orphie	Orphie	Octoraro Orphie	
3	wiarton-willie	Willie	Wiarton Willie	
4	jimmy-the-groundhog	Jimmy	Jimmy the Grour	
5	concord-charlie	Charlie	Concord Charlie	

id <dbl></dbl>	slug <chr></chr>	shortname <chr></chr>	name <chr></chr>
6	buckeye-chuck	Chuck	Buckeye Chuck
6 rows 1-5 of 17 columns			

join terminology

There are two main types of join:

- mutating joins add variables from one dataframe to another based on matching characteristics between the two
- **filtering joins** subset one dataframe based on matching characteristics with another dataframe

join terminology 🦠

- Every join involves a **primary key** and a **foreign key**
 - A primary key is a variable or set of variables that uniquely identifies an observation
 - A foreign key is just another table's primary key that matches your tables' primary key. It might have a different name or be spread across more or less variables.
- The first step when joining data is to identify the primary and foreign keys you'll work with
- Always check that your primary & foreign keys are truly unique to each row!

groundhog_id	shadow_percent
<dbl></dbl>	<dbl></dbl>
1	0.8437500
2	0.7912088
3	0.4166667
3 rows	

id	slug	shortname	name
<dbl></dbl>	<chr></chr>	<chr></chr>	<chr></chr>
1	punxsutawney-phil	Phil	Punxsutawney Phil
2	octoraro-orphie	Orphie	Octoraro Orphie
3	wiarton-willie	Willie	Wiarton Willie
	s 1-5 of 17 columns	vviiile	vviaiton vviine

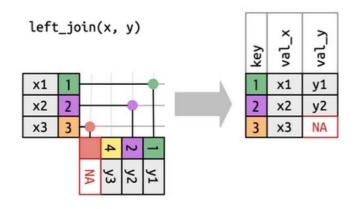

- How would we determine if there is a difference between the average shadow prediction rate of different types of groundhogs?
- primary key: groundhog_id in groundhog_predictions
- foreign key: id in groundhogs

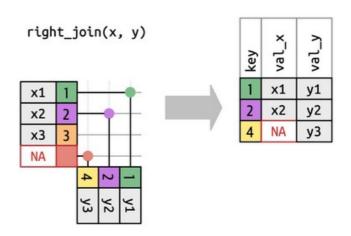

- We want to add the variables from groundhogs to our groundhog_predictions table
- We'll need a **mutating join**, specifically a **left join**.
- A **left join** retains all rows in the left dataframe, and adds additional data in from the right dataframe if the keys match.
- left_join(x, y, join_by(x.key == y.key))

1 left_join(groundhog_predictions,	groundhogs, join	_by(groundhog_id == id))	
groundhog_id <dbl></dbl>	shadow_percent <dbl></dbl>	3	
1	0.84375000	punxsutawney-phil	
2	0.79120879	octoraro-orphie	
3	0.41666667	wiarton-willie	
4	0.41818182	jimmy-the-groundhog	
5	0.40000000	concord-charlie	
6	0.30000000	buckeye-chuck	
7	0.10000000	general-beauregard-lee	
8	0.34285714	french-creek-freddie	
9	0.33333333	gertie-the-groundhog	
10	0.32142857	dunkirk-dave	
1-10 of 60 rows 1-4 of 18 colu Previous 1 2 3 4 5 6 Next			

more mutating joins

right_join() keeps everything in the right dataframe
and adds in data from the left

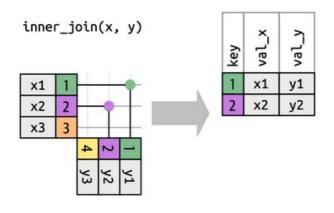

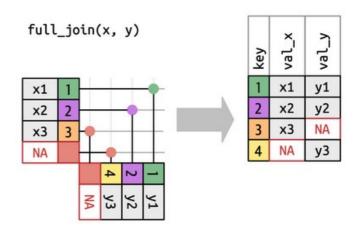

more mutating joins

inner_join() keeps rows with keys that appear in both
dataframes

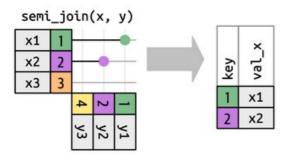

full_join() keeps all rows from both dataframes

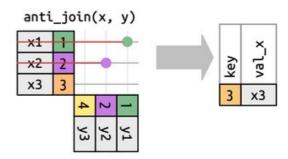

filtering joins

filtering joins subset one dataframe based on matching characteristics with another dataframe. In filtering semi_join(x, y) keeps all rows in x with a match in y anti_join(x, y) returns all rows in x without a match in y

join exercises

- groundhog_predictions contains one row per 50 unique groundhogs
- groundhogs contains one row per 65 unique groundhogs
- Every groundhog in groundhog_predictions appears in groundhogs
 - How many rows would each of the following joins have: right join with groundhogs on the right, inner join, full join, semi_join, anti_join?

more complex join conditions

- Within join_by(), we can use more complex conditions than whether key == key
- You can use other numeric operations like >, <, etc.
- The closest() function matches the closest key to another key based on some criteria (closest value at all, closest value that is larger, etc.)
- between() and within() can test whether a value falls between two other values. This is useful if you want to join events that happened within a given time span.

other table verbs

- bind_rows() pastes rows onto the bottom of a dataframe
- bind_cols() pastes columns onto the right of a dataframe.
- There are no conditions in these functions, you can think of them as copy-and-paste.

Let's put everything we've learned together!

Let's create a summary table that gives the rate at which each type of groundhog sees its' shadow

finish line

Groundhog

type <chr> Ameraucana chicken Animatronic groundhog Armadillo Atlantic lobster Beaver Bullfrog Cat

1-10 of 26 rows | 1-4 of 5 columns

Previous 123 Next

Donus exercises

- Write code to calculate the column predictions_count in groundhogs
- Write code to calculate the column is_groundhog in groundhogs
- Calculate the proportion of groundhogs from each country that make predictions each year
- Add a column to groundhogs indicating the first year each groundhog saw its shadow

summary: verbs & helper functions

Verbs:

- filter(), arrange(), distinct()
- group_by(),summarize()
- mutate(), select(), rename()
- left_, right_, inner_, full_, semi_, anti_ joins
- bind _rows and _cols

Helper functions:

- desc()
- n(), n_distinct(),
 min(), max(), sum()
- if_else() and case_when()
- between() and within()
